Genetically predicted circulating levels of copper and zinc are associated with osteoarthritis but not with rheumatoid arthritis

J. Zhou † ‡, C. Liu † §, Y. Sun †, M. Francis † ‡, M.S. Ryu †, A. Grider #, K. Ye † || *

Objective: Osteoarthritis (OA) and rheumatoid arthritis (RA) are both debilitating diseases that cause significant morbidity and disability globally. This study aims to investigate the causal effects of varying blood levels of five minerals—iron, zinc, copper, calcium, and magnesium, on OA and RA.

Design: We performed two-sample Mendelian randomization (MR) analyses to assess the associations of five circulating minerals with OA and RA. Single nucleotide polymorphisms (SNPs) serving as genetic instruments for the circulating mineral levels were selected from large genome-wide association studies of European-descent individuals. The associations of these SNPs with OA and RA were evaluated in UK Biobank participants. Multiple sensitivity analyses were applied to detect and correct for the presence of pleiotropy.

Results: Genetically determined copper and zinc status were associated with OA, but not with RA. Per standard deviation (SD) increment in copper increases the risk of OA (OR = 1.07, 95% CI: 1.02–1.13) and one of its subtypes, localized OA (OR = 1.08, 95% CI: 1.03–1.15). Per SD increment in zinc is positively associated with risks of OA (OR = 1.07, 95% CI: 1.01–1.13), generalized OA (OR = 1.18, 95% CI: 1.05–1.31), and unspecified OA (OR = 1.21, 95% CI: 1.11–1.31). Additionally, per SD increment in calcium decreases the risk of localized OA (OR = 0.83, 95% CI: 0.69–0.98).

Conclusions: Genetically high zinc and copper status were positively associated with OA, but not with RA. Given the modifiable nature of circulating mineral status, these findings warrant further investigation for OA prevention strategies.

Introduction

Osteoarthritis (OA) and rheumatoid arthritis (RA) are two different types of arthritis, both manifested with inflammation. OA is the most common joint disease worldwide, affecting an estimated 3.8% of the global population. It is characterized by degraded cartilage, moderate synovial inflammation, alteration of bony structure, pain, and impaired mobility. RA is estimated to affect approximately 0.24–1% of the population and is twice as common in women than men. It is a chronic autoimmune disease characterized by inflammatory polyarthritis that preferentially affects the small joints. The clinical symptoms of OA and RA are similar and sometimes difficult to distinguish, although there are significant differences in their pathogenesis. A variety of genetic and environmental factors have been linked to the development and progression of these two diseases. While many of these risk factors are difficult to change, some may be more amenable to medical and behavioral interventions (e.g., nutrition). Poor nutrient status in OA or RA patients has been reported, and minerals may affect these two diseases through their cofactor roles in immune functions and different metabolic processes in joint tissues.

Minerals are a diverse group of substances constituting enzyme complexes and participating in a variety of fundamental physiological activities. Naturally occurring minerals, such as iron (Fe),
calcium (Ca), magnesium (Mg), copper (Cu), and zinc (Zn), have been implicated in different inflammatory effects in both animal and human studies. Zinc can function as an anti-inflammatory agent, and clinical manifestations of zinc deficiency include growth retardation, immune dysfunctions, increased oxidative stress, and enhanced production of proinflammatory cytokines. Chronic intake of a large quantity of zinc may interfere with copper absorption, reduce the levels of high-density lipoprotein cholesterol, and impair immune responses. Furthermore, copper is essential for iron absorption, and thus copper deficiency can impair iron metabolism. Iron is indispensable for the immune cell proliferation, particularly that of lymphocytes, in response to infection. Likely due to their close interactions, different minerals are usually found to be associated with similar diseases. Elevated blood iron and copper levels are positively with the risk of OA23, while those of calcium and magnesium are inversely associated its risk24. Copper and zinc have been reported to be positively correlated with RA25. Due to the fact that most studies were observational and may suffer from reverse causality and residual confounding, it remains uncertain whether these associations indicate causal relationships.

Mendelian randomization (MR), a complementary approach to epidemiological observations, uses genetic variants as instrumental variables to investigate the causal association between circulating minerals and RA. Genetic instruments for mineral status were selected from recent genome-wide association studies (GWAS) of blood minerals in participants of European descent, and the mean F-statistic was 0.37% of the variance for blood calcium levels, and the mean F-statistic was 64. The genetic variants for erythrocyte copper and zinc levels were derived from the Queensland Institute of Medicine’s twins and their families (N = 2,603)26. Collectively, we selected two significant SNPs (P < 10^{-10}) associated with blood copper concentration, which accounted for 5% of the phenotypic variance for copper, and the mean F-statistic was 62. For zinc, two SNPs were selected as instrumental variables, explaining 4.59% variance for its concentration, and the mean F-statistic was 61. We excluded X-linked SNP rs4826508 to avoid invalid instruments because its different allele frequencies in male (0.89) and female (0.79) are statistically significant. Summary-level data (beta coefficients and standard errors) for the associations of the selected SNPs with each mineral from different GWAS cohorts were listed in Table I.

Ascertainment of osteoarthritis and rheumatoid arthritis

The associations of selected genetic instruments with OA and RA were estimated in UK Biobank. Diagnosed diseases status was recorded in the hospital episode statistics as the International Classification of Diseases (ICD) codes. We mapped these ICD codes to the pheno group system, which merges related codes into relatively independent and clinically meaningful groups. The pheno system provides a scheme to automatically define case and control status for each pheno by excluding participants with similar or potentially overlapping disease states from the corresponding control group. The pheno code 740.1 was used for RA (N = 36,612 cases; 274,387 controls), while the pheno 714.1 was used for OA (N = 3,547 cases; 308,452 controls). In addition, the pheno codes of 740.1, 740.2, and 740.9 were used for OA subcategories: localized (N = 30,741 cases; 280,258 controls), generalized (N = 5,617 cases; 305,382 controls), and unspecified (N = 9,949 cases; 301,050 controls), respectively.

All analyses were restricted to participants of genetically European descent to maintain consistency with the European samples used to obtain genetic instruments for circulating mineral status. We quality-controlled and filtered the UK Biobank dataset by removing individuals whose genetic ancestry is not Caucasian, or who are not included in the genetic principal component analysis, or who have sex chromosome aneuploidy. To avoid bias from related individuals, one participant from each pair of relatives was excluded based on a kinship coefficient of >0.0884. Logistic regression analysis was performed for each instrument SNP separately across all OA and RA phecodes, adjusting for age, sex, genotyping array, assessment center, and the first ten genetic principal components. Genetic principal components were included to explicitly account for possible population stratification. They have been pre-calculated based on selected genome-wide genotype markers.

Statistical analysis for MR estimates

The estimates of the causal effect were obtained using the inverse variance-weighted (IVW) method. Effect estimates were...
and it also offers an unbiased estimate of the causal effects while intercept test for the presence of unbalanced horizontal pleiotropy, conducted using the MendelianRandomisation and TwoSampleMR packages and the R programming language.

Results

Genetically predicted higher copper and zinc status was positively associated with OA, but not with RA (Fig. 1). The ORs of OA were 1.07 (95% CI: 1.02–1.13; P = 0.01) and 1.07 (95% CI: 1.01–1.13; P = 0.02), per one SD increment in erythrocyte copper and zinc levels, respectively. Cochran Q tests did not find evidence of heterogeneity (Supplementary Table 1). The associations of calcium, iron, and magnesium levels with OA did not reach the significance level at P < 0.05. On the other hand, genetic predisposition to high circulating levels of all these blood minerals showed no significant associations with RA. Detailed analysis on the subcategories of OA, including localized, generalized, and unspecified OA, unraveled evidence of causal associations with copper, zinc, and calcium (Fig. 2, Supplementary Table 2). Per SD increment in copper is associated with increased risks of localized OA (OR = 1.08, 95% CI: 1.03–1.15, P = 0.003). Per SD increment in zinc is positively associated with risks of generalized OA (OR = 1.18, 95% CI: 1.05–1.31, P = 0.014), and unspecified OA (OR = 1.12, 95% CI: 1.11–1.13, P = 0.0002). In contrast to the risk-increasing effect of copper and zinc, per SD increment in calcium decreases the risk of localized OA (OR = 0.83, 95% CI: 0.69–0.98, P = 0.021). For all these estimates, Cochran Q tests did not find evidence of heterogeneity. Additionally, for the effect of calcium on localized OA, the intercept test in MR-Egger did not find evidence of unbalanced pleiotropy, and the WM MR also revealed a significant estimate (OR = 0.84, 95% CI: 0.71–0.98, P = 0.042).

We further performed sex-stratified IVW MR analysis to identify sex-specific causal effects of these five minerals. That is, their MR estimates are significant only in one sex group, but not in the other or the sex-combined sample. In males, per SD increment in serum iron is associated with increased risk of unspecified OA (OR = 1.27, 95% CI: 1.05–1.54, P = 0.013), but serum calcium is negatively associated with the risk of OA (OR = 0.67, 95% CI: 0.46–0.98, P = 0.038), RA (OR = 0.35, 95% CI: 0.14–0.86, P = 0.02) and generalized OA (OR = 0.35, 95% CI: 0.13–0.93, P = 0.035). No sex-specific effects were found for copper, zinc, and magnesium. All these sex-specific causal estimates do not have indications of

A forest plot showing associations between three minerals and three OA subcategories based on MR analysis. The causal estimates are from IVW MR and have no indications of pleiotropy. The odds ratios (ORs) with their 95% confidence intervals (CIs) are scaled to 1-SD increase in blood mineral level. Complete MR results between all five minerals and the three OA subcategories are provided in Table S2. No significant associations were found for iron or magnesium.
heterogeneity across genetic instruments (Supplementary Table 3). We additionally performed a sensitivity analysis without adjustment for sex, and the results showed no difference in the significance of MR associations when compared to that with adjustment for sex.

**Discussion**

In this study examining the causality of five circulating minerals (i.e., iron, calcium, magnesium, zinc, copper) on OA and RA, we found that genetically predicted high levels of copper and zinc were positively associated with OA, but not RA. There was some evidence supporting a causal role of iron and calcium on OA, especially in males. No causal associations were found for RA, except a suggestive protective effect of calcium in males. Across combined and sex-stratified analyses, we found that copper, zinc, and iron increase, while calcium decreases the risks of OA and/or its subtypes. Of note, the effects of iron and calcium on OA were also reported in two independent MR studies. Among these minerals, zinc has the best-elucidated mechanism. OA is primarily characterized by cartilage destruction, with the extracellular matrix degraded by zinc-dependent matrix-degrading enzymes (e.g., MMP3, MMP9, MMP12, MMP13, and ADAMTS5). In human chondrocytes, zinc influx upregulates a zinc-activated transcription factor, MTF1, which then induces expression of matrix-degrading enzymes, causing cartilage destruction. For iron, a longitudinal cohort study observed that increased serum ferritin is associated with symptomatic knee OA incidence and severity in males. Mechanistically, iron overload in a murine model of hereditary hemochromatosis enhances the expression of MMP3 and is associated with accelerated OA progression under mechanical stress. These are consistent with our male-specific MR result of iron on OA. For copper, few published studies examined its effects on OA. We only found one small study reporting elevated plasma and synovial copper concentrations in OA patients when compared to healthy controls, but their pathological roles are still elusive. In contrast to the risk-increasing effect of the other three minerals, calcium is protective against OA in our MR results, especially in men. In a previous cross-sectional study, serum calcium concentration was inversely associated with knee OA, but their pathological roles are still elusive. In contrast to the risk-increasing effect of the other three minerals, calcium is protective against OA in our MR results, especially in men. In a previous cross-sectional study, serum calcium concentration was inversely associated with knee OA, but a null association was also reported. A randomized controlled trial showed the benefit of vitamin D supplements on knee OA and found that the serum calcium level increased after treatment. All of these existing studies suggest that blood minerals play important roles in the pathogenesis of OA. In general, the study findings call for further clinical intervention for preventing OA, especially zinc, copper and iron. It also demonstrates that not all minerals associated with OA in observational research are causal, advising against their usage in clinical prevention. Overall, our findings pinpoint the prominent roles of blood minerals in the pathogenesis of OA, calling for further confirmative and mechanistic studies.

**Author contributions**

JZ and KY conceived and designed the study. JZ, CL, and YS performed statistical analyses. MF managed and curated the UK Biobank dataset. All authors interpreted the results. JZ and KY drafted the manuscript. All authors edited the manuscript for
intellectual content. All authors take responsibility for the integrity of the study.

Funding

AG is supported by the United States Department of Agriculture, National Institute of Food and Agriculture Hatch Funds.
